ABSTRACT

We present Atacama Large Millimetre Array and Atacama Compact Array observations of the Sunyaev-Zel'dovich effect in the $z = 2$ galaxy cluster Cl J1449+0856, an X-ray-detected progenitor of typical massive clusters in the present day Universe. While in a cleaned but otherwise untouched 92 GHz map of this cluster, little to no negative signal is visible, careful subtraction of known sub-millimetre emitters in the uv plane reveals a decrement at 5σ significance. The total signal is $-190 \pm 36 \mu\text{Jy}$, with a peak offset by $5''$ – $9''$ (~ 50 kpc) from both the X-ray centroid and the still-forming brightest cluster galaxy. A comparison of the recovered uv -amplitude profile of the decrement with different pressure models allows us to derive total mass constraints consistent with the $\sim 6 \times 10^{13} M_{\odot}$ estimated from X-ray data. Moreover, we find no strong evidence for a deviation of the pressure profile with respect to local galaxy clusters, although a slight tension at small-to-intermediate spatial scales suggests a flattened central profile, opposite to what seen in a cool core and possibly an AGN-related effect. This analysis of the lowest mass single SZ detection so far illustrates the importance of interferometers when observing the SZ effect in high-redshift clusters, the cores of which cannot be considered quiescent, such that careful subtraction of galaxy emission is necessary.

Key words. galaxies:clusters:individual:Cl J1449+0856 – galaxies:clusters:intracluster medium

1. Introduction

The study of distant galaxy clusters has experienced a dramatic advance in the past decade, with the discovery of the first $z \sim 2$ clusters (Andreon et al. 2009; Gobat et al. 2011) and the subsequent breaching of that redshift limit into what was then considered then the epoch of protoclusters (Spitler et al. 2012; Yuan et al. 2014; Wang et al. 2016). It is now possible to efficiently identify galaxy clusters at $z > 2$ in selected areas of the sky (e.g., Chiang et al. 2014; Strazzullo et al. 2015; Daddi et al. 2017), as well as select relatively large samples up to $z \lesssim 2$ (e.g., Willis et al. 2013; Bleem et al. 2015). We are thus leaving the discovery stage and are now becoming able to characterise the physical properties of these structures, with an eye toward answering longstanding questions regarding their baryonic content, such as the early evolution of their gaseous atmosphere (i.e., their intracluster medium, or ICM) and its interaction with their stellar component. The injection of energy into the ICM from star formation or active galactic nuclei (AGN) is a long-standing topic (Kaiser 1991; Ponman et al. 1999; Valageas & Silk 1999; Tozzi & Norman 2001). However, high-redshift constraints are difficult to set, except indirectly in special cases (e.g., Valentino et al. 2016), as both common methods for

observing the ICM are less effective at higher redshift. X-ray observations, being limited by surface brightness, succumb to the inverse square law. The Sunyaev-Zel'dovich effect (SZ), on the other hand, is in principle distance-independent and has indeed yielded secure detections up to $z \sim 2$ (Brodwin et al. 2012; Mantz et al. 2014, 2018). However, since the thermal SZ effect scales with electron density in the ICM, observations and surveys are still naturally biased towards massive ($\gtrsim 10^{14} M_{\odot}$) systems. These not only become increasingly rare at higher redshift, but are also typically dominated by well-established quiescent galaxy populations (e.g., Stanford et al. 2012; Newman et al. 2014), i.e., well past the stage where we would expect most of early energy injection to occur.

Cl J1449+0856 (hereafter Cl1449) is a young galaxy cluster at $z = 1.995$ (Gobat et al. 2013) and one of the most distant with detectable X-ray emission. Serendipitously detected as an overdensity of red galaxies in *Spitzer*/IRAC near-infrared imaging ($m_{3.6} - m_{4.5} > 0$; Gobat et al. 2011), it is a compact structure that already hosts a significant population of massive, quiescent galaxies (Strazzullo et al. 2013, 2016), but also copious amounts of star formation as well as a > 100 kpc Ly α emission nebula in its core (Valentino et al. 2016). The presence of a colder

($T \sim 10^4$ K) gas phase coexisting with the hot ($T \sim 10^6$ K) ICM points to either a cool core (e.g., Heckman et al. 1989), which would be surprising at this early stage in the cluster’s evolution, or feedback and maintenance from galactic outflows powered by either star formation or AGN (Valentino et al. 2016). In terms of mass, C11449 is a typical Coma progenitor at $z \sim 2$ and therefore offers a window on the early thermodynamic evolution of typical galaxy clusters as well as the opportunity to study galaxy feedback to the ICM in a developing structure. We thus approach the SZ effect in this cluster from two different perspectives: as yielding an independent constraint on its total mass, providing a test for scaling relations at $z \sim 2$ as well as a clearer picture of its place in galaxy cluster evolution, and as a probe of the thermodynamic status of its diffuse gas component.

Here we present ~ 92 GHz observations of C11449 carried out with the Atacama Large Millimetre Array (ALMA) and the Atacama Compact Array (ACA), building upon recent work at millimetre and radio wavelengths (Strazzullo et al. 2018; Coogan et al. 2018, 2019, hereafter S18 and C18, respectively). We describe the observations in Section 2, the analysis of the data in Section 3, and discuss its implication in Section 4, while Section 5 summarises our findings. We assume a Λ CDM cosmology with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.3$, and $\Omega_\Lambda = 0.7$ throughout. Stellar masses and star formation rates (SFR) assume a Salpeter (1955) initial mass function.

2. Observations and data reduction

C11449 was observed with ALMA and ACA in Cycle 4 under program 2016.1.01107 (PI Gobat). The observations, which are summarised in Table 1, were carried out between November 2016 and March 2017 as single pointings with total observing times of 49h for ACA and 9.7h for ALMA. The data were taken in Band 3, with a central frequency of 92 GHz and a phase centre at R.A. = 14:49:14 and Dec = 8:56:26. Although not probing the peak of the SZ decrement, this frequency was chosen as a compromise to both optimise the total integration time and minimise positive contamination by the redshifted far-infrared emission from cold dust in star forming cluster members or high-redshift interlopers (Fig. 1). Our target of interest being extended, possibly over a scale of several tens of arcseconds, we chose the most compact ALMA configuration to minimise signal loss due to over-resolution (the maximum recoverable scale being $29''$ in cycle 4) and probe large spatial scales. This is aided by our choice of frequency, generating the widest beam currently possible for both ALMA and ACA. As a result, the ACA and ALMA maps have synthesised beams of $\text{FWHM}_{\text{ACA}} \sim 16.86'' \times 13''$ and $\text{FWHM}_{\text{ALMA}} \sim 4.23'' \times 3.58''$, respectively, with a r.m.s. (root mean square) point-source sensitivity of ~ 22 and $\sim 4 \mu\text{Jy/beam}$, respectively.

We reduce the raw data using the CASA software suite (McMullin et al. 2007) and the script provided by ALMA to generate measurement sets (one per spectral window per array), which were merged into a single UVFITS table per array, for subsequent analysis with the GILDAS¹ software suite. We use natural weighting for imaging throughout the paper. These data show, at first glance, little to no SZ signal (Fig. 2, A and B). This is not surprising as the field of C11449 is overdense in FIR sources, both within the cluster and in the

Fig. 1. SZ decrement as a function of frequency, scaled to our observed 92 GHz value (see Section 3), with a MS SED at $z = 2$ for comparison (blue curve; Magdis et al. 2012). The red dots show the 92 GHz fluxes of point sources within the field of C11449, while the dark tan bands mark the frequency windows of our observations (lower and upper sub-band, respectively).

Table 1. Summary of ALMA and ACA observations of C11449

	total time (h)	r.m.s. ($\mu\text{Jy/beam}$)	beam size ($''$)
ALMA	9.7	4	4.23×3.58
ACA	49	22	16.86×13

background (S18; Smith et al. 2019). Despite our choosing a low frequency to mitigate the problem, the combined flux of high-redshift dusty sources is thus sufficient to fill the SZ decrement. We therefore subtract, from the data, point sources at the positions of 9 known FIR emitters (Table A.1). This is done on visibilities, i.e., in (u, v) space. To determine the positions and fluxes of the sources, we use higher-resolution ALMA $870 \mu\text{m}$ and CO(4–3) observations of C11449 (described in C18). We first measure their fluxes in the higher-resolution 92 GHz ALMA data, using only visibilities with uv -distance ($\sqrt{u^2 + v^2}$; hereafter uv) of $uv > 30 \text{ m}$, i.e., considering only small spatial scales. These fluxes do not change significantly if we adopt a more stringent cut, such as $uv > 50 \text{ m}$ (corresponding to $\sim 100 \text{ kpc}$). The sources are then subtracted from both the ALMA and ACA 92 GHz data (this time over the whole uv range), at the same fixed positions. In both cases we model them as point sources, since the beams are large compared to the sizes found in C18. Where possible we model and subtract the sources by groups of 4, iteratively from brightest to faintest, to minimise contamination. As a sanity check, we also compare the recovered fluxes to the 92 GHz expectations from Magdis et al. (2012) spectral energy distribution (SED) templates, finding consistency (Fig. A.1). A merged ALMA+ACA map of the resulting data is shown in Fig. 2 (C), which shows a noticeable negative signal. Since only galaxies detected in either ALMA continuum or line emission maps were subtracted from the ALMA and ACA observations, some residual positive signal from below-threshold faint and/or low-mass galaxies might be still present in the data. The amplitude, and significance thereof, quantified in Section 3 can thus be considered as conservative.

¹ <http://www.iram.fr/IRAMFR/GILDAS>

Fig. 2. *Top:* ACA (A) and ALMA (B) 92 GHz maps of the field of C11449 before point-source subtraction, created from the data using the CASA routine CLEAN. The white cross marks the centroid position of the extended X-ray emission seen by *Chandra* while the grey circle shows the positions of the still-forming central galaxy of the cluster. The positions of all subtracted point sources are shown by diamonds (orange for confirmed cluster members, green with labels for confirmed or possible interlopers). For comparison, the dotted white contour marks the extent of the ALMA observations described in C18 and S18. *Bottom:* combined ACA+ALMA 92 GHz image after subtracting point sources (C), showing the SZ signal from the cluster’s ICM. The black square shows the field of view of panels A, B, and D, and the white-filled magenta ellipse the average synthesised beam size. Panel D shows a *HST*/WFC3 colour composite (F105W, F140W, and F160W) image of C11449 for comparison. The dashed grey contours display the X-ray emission as seen by *Chandra*, while the light green contours shows the SZ signal above the r.m.s. noise.

3. Analysis

For both the ALMA and ACA data we extract fluxes by fitting, in bins of uv , the complex visibilities with a point source using the UV_FIT task GILDAS. We choose the point-source model for simplicity, as it corresponds in (u, v) space to $V(u, v) = \text{constant} \times e^{-2\pi i(ux+vy)}$, where (x, y) is the position of the source with respect to the phase centre and (u, v) are here in units of cycles/distance. At phase centre, this is equivalent to averaging visibility amplitudes within the chosen uv range. However, we give (u, v) in metres throughout the text

for convenience, using the central frequency to convert these coordinates into distances. We first perform the fit in a large bin of $uv = 6 - 25$ m, leaving the offset (x, y) free to determine the location of the peak of the signal, then extract fluxes at fixed position in uv bins of 6–13.5 m, 13.5–18.75 m, 18.75–25.5 m, 25.5–50 m, 50–100 m, and 100–300 m. We do not take the formal errors on the point-source fit as uncertainties to the signal in each uv bin, but instead use the r.m.s. noise as measured in each bin with a point-source fit at randomised large offset positions. This yields slightly larger error bars on average. The resulting

uv -amplitude profile, shown in Fig. 3, displays a negative signal in the $uv \sim 6 - 30$ m range, i.e., at angular scales $\gtrsim 200$ kpc. When combining ALMA and ACA visibilities, the total signal over all angular scales is $-190 \pm 36 \mu\text{Jy}$, with a significance of 5.3σ . Including the errors on the fluxes of subtracted sources, weighted by their positions with respect to the best-fit pressure model (see Section 4), would conservatively add another $\sim 4 \mu\text{Jy}$ in quadrature to the uncertainty, which does not strongly affect the level of significance of the SZ detection. Prior to the subtraction of positive sources, on the other hand, the SZ signal is only $\sim -20 \mu\text{Jy}$, i.e., is almost entirely filled, with only the shortest uv distances providing any tentative hint of a SZ decrement. If, on the other hand, we only remove sources which are either known to be interlopers or have not been conclusively proven to be at the cluster's redshift (i.e., A3, A4, A5, and BRG in Table A.1), a signal is marginally detected at $-123 \pm 40 \mu\text{Jy}$. The filling of the decrement by confirmed cluster members thus amounts to $\sim 35\%$ of the signal, possibly more if either one of the unconfirmed sources (A4 and A5) is associated with the cluster. Assuming that C11449 is representative of its halo mass range and redshift, this test can be understood as an ideal unsubtracted case where no bright FIR interlopers are present along the cluster's line of sight. However, we currently have no reason to think that the field of C11449 is particularly overdense in FIR sources with respect to other, as-yet undiscovered clusters of its size and epoch. We also note a slight tension between the ALMA and ACA profiles within their range of overlap (Fig. 3, B), with the latter showing more decrement than the former. This cannot in principle be explained by differences between the two instruments, as simulated observations (see Section 3.1) would rather suggest an opposite trend than the one observed, and might perhaps be due to a calibration issue. On the other hand, the significance of this difference is small enough ($\sim 1.5\sigma$) that it can safely be attributed to noise.

C11449 had previously been observed at 31 GHz with the Combined Array for Research in Millimeter-wave Astronomy (CARMA). This observation, which has a r.m.s. noise of $90 \mu\text{Jy}/\text{beam}$, did not yield a detection aside from some positive emission. Here we revisit the CARMA data and perform a similar point-source subtraction (Appendix C) as discussed above. We find a loose constraint for the SZ signal of $\gtrsim -360 \mu\text{Jy}$ at 3σ , which is certainly consistent with the expectation of $\sim -32 \mu\text{Jy}$ from the 92 GHz data when assuming a standard spectral shape. On the other hand, Mantz et al. (2014) report a secure detection of the similar-redshift cluster XLSSU J021744.1-034536 (hereafter XLSSC 122) with the same instrument and central frequency, but a $\sim 68\%$ larger integration time, matching its much larger mass.

The peak of the weighted-average ALMA+ACA signal is offset from the phase centre by $\Delta(RA, DEC) = (4.4, 4.3)''$, which translates into a separation of $4.7''$ from the forming brightest cluster galaxy (BCG) and $9.5''$ with respect to the peak of the X-ray emission, i.e., the putative centre(s) of mass of the cluster (Fig. 2, panels C and D). Interestingly, Mantz et al. (2014) also report an offset between the SZ signal and the BCG of XLSSC 122, which is of comparable amplitude when accounting for the different beam sizes of both datasets. That detection is consistent across different observations (Mantz et al. 2018) and thus rather unlikely to be a product of noise. Offsets of this amplitude between either the BCG or X-ray peak and the SZ centroid are not unexpected, especially in clusters that are in an unrelaxed state (e.g., Zhang et al. 2014) as we would expect C11449 to

be given its relative youth, and are commonly observed in high-redshift clusters (e.g., Brodwin et al. 2016; Strazzullo et al. 2019). We perform a Monte Carlo simulation to estimate the significance of this offset (see Appendix B), subtracting the combined astrometric uncertainty of ACA/ALMA and *Chandra* in quadrature. We find that the difference between the SZ peak and the BCG positions is well within the normal variation of the simulation, while the offset between the SZ and X-ray peaks falls within the top 1.5% of realisations, corresponding to a significance of at most 2.4σ . We therefore still cannot discount the possibility that this observed discrepancy between the peaks of the SZ and X-ray signals is simply due to random noise.

3.1. Modelling

To investigate the characteristics of the ICM in C11449 and link the observed SZ signal to actual physical properties of the cluster, such as total mass, we fit the uv -amplitude profile extracted from the ALMA and ACA data to a range of models with freely varying amplitudes. We first consider several models of the electron pressure profile of the ICM based on a generalised Navarro-Frenk-White functional form (GNFW; Nagai et al. 2007) with fixed parameter values:

- the theoretical median profiles from Le Brun et al. (2015, hereafter LB15) based on cosmological hydrodynamical simulations, with different levels of feedback from AGN. In that paper, they are referred to as REF, AGN 8.0, and AGN 8.5. The last two, as the names suggest, include a prescription for AGN feedback with increasing intensity, while the REF model does not.
- the empirical Arnaud et al. (2010) profile (hereafter A10), derived from local $> 10^{14} M_\odot$ galaxy clusters. This is also the profile used by Mantz et al. (2018) to fit the SZ signal of the $z = 1.99 \pm 0.06$ cluster XLSSC 122 and thus allows for direct, easy comparison with both this study and the low-redshift universe. For completeness, we also include the empirical profile from Sayers et al. (2016, hereafter S16), which is based on A10 but with a different outer slope. We adopt $\beta_{\text{GNFW}} = 6.13$ as given in that paper, but note that S16 also find a mass and redshift dependence to the slope β_{GNFW} which, for C11449, would correspond to its A10 value.
- the empirical “high- z ” profile from McDonald et al. (2014, hereafter McD14), which is based on a sample of $z = 0.6 - 1.2$, $> 10^{14} M_\odot$ galaxy clusters observed with the South Pole Telescope. It differs from the A10 profile mainly by being flatter (i.e., having less pressure) at small radii. We consider both the cool core and non-cool core versions of this profile.

For each model we create a map of the intrinsic signal by projecting the profile on the plane of the sky at the coordinates of the cluster, including an average Compton- y background of 1.6×10^{-6} derived from the 25 deg^2 simulated maps described in LB15. For simplicity all models are spherical, i.e., axisymmetric when projected. We also consider the contribution of a gravitationally lensed infrared background to the decrement. However, we estimate it to be minute ($< 0.1\%$; Appendix D) due to a combination of low halo mass, decreasing lensing efficiency at higher redshift, and low 92 GHz background density. We use the 2D models as inputs for noise-free simulations of ACA and ALMA observations using the *simalma* task in CASA, taking care to adopt the same integration times and hour angles as with the data. We then compare the model and data visibilities, merging the ALMA and ACA deviates as the last step. While

we keep the GFW parameters fixed to the various models' values, we let the mass vary freely. However, while the models are given in function of M_{500} , our previous works (Gobat et al. 2011; Valentino et al. 2016) instead discuss the “total” mass M_{200} . We here therefore extrapolate M_{200} from M_{500} , assuming that the mass distribution follows the GFW profile. The fits of the A10, LB15, S16, and McD14 models to the observed uv -amplitude profile are shown in Fig. 3.

Additionally, we also attempt a parametric fit using the simpler β -model historically used to describe the X-ray luminosity profiles of galaxy clusters (Cavaliere & Fusco-Femiano 1978), leaving both the core radius r_c and the index β free to vary. For practicality, in this case we fit the ALMA and ACA visibilities with the forward Fourier transform of each β -model sampled at the same (u, v) positions as the data. At our signal-to-noise ratio (S/N) this is essentially equivalent to the full *simalma* model (see Appendix E), and allows us to explore the parameter space of the models more rapidly and at little to no detriment to precision.

4. Results and discussion

We find that the McD14 profile matches the observed data best, as determined by its χ^2 value, followed by A10 and the AGN-feedback LB15 models with only the REF one falling below the $\sim 2\sigma$ confidence level. Most suggest total cluster masses that are consistent with the *Chandra* constraint of $M_{200} \sim 6 \times 10^{13} M_\odot$ (Valentino et al. 2016) (Fig. 4), i.e., at least a factor ~ 2 below the limit of typical SZ surveys at any redshift (Bleem et al. 2015; Planck Results XXVII; Hilton et al. 2018). Among the various models considered, only AGN 8.5 yields a higher mass of $\sim 1.8 \times 10^{14} M_\odot$. In this case, the somewhat higher value is unsurprising since, in the models, the gas fraction decreases with increasing AGN feedback as more material is ejected, thereby requiring a higher mass to reproduce the same integrated signal. Overall, the constraining power of the observed uv -amplitude profile with respect to the pressure model is somewhat limited, especially at large scales/small baselines where the GFW models appear to be equivalent to one another, in part due to the relatively modest S/N of the data. Of the fixed-parameter models, only the McD14 one fits noticeably better, at intermediate uv . We also note that the profile can be reproduced best with a β -model (Fig. 3, B), which is unsurprising as it has two additional free parameters. However, owing to parameter degeneracy (see Appendix F, Fig. F.1), the constraints it provides remain loose as well, with $(r_c, \beta) \gtrsim (100 \text{ kpc}, 0.4)$. Nevertheless, we note that the core radius r_c is consistently large, of the order of the (putative, X-ray derived) r_{500} of the cluster whereas, by comparison, the galaxy density profile has $r_c \sim 20 \text{ kpc}$ (Strazzullo et al. 2013). Consequently, the best-fitting profiles are essentially flat at $\lesssim 0.3r_{500}$ (i.e., in the inner $\sim 150 \text{ kpc}$; Fig. 5).

This is due to the apparent lack of power of the observed profile at $uv \sim 30 \text{ m}$ (corresponding to $\lesssim 10''$), which only the McD14 profile reproduces at all uv within the uncertainties of the data (the non-cool core and cool core versions of the profile show here little difference; Fig. 3, B). The other GFW models only fit completely if we force the projected signal to be constant (i.e., flat) within the inner $\sim 15''$ (see Fig. 3, B). Assuming for the sake of speculation that this flatness at intermediate and large uv distances is not simply due to noise fluctuations, as suggested

by the evolution observed in higher-mass (but lower-redshift) clusters (Battaglia et al. 2012, McD14), at least two different causes can be envisioned. On the one hand, left-over flux from incomplete point source subtractions could indeed remove power from the SZ signal at small scales. This might either arise from an underestimate of the (here, 92 GHz) flux of detected star-forming sources or from the emission of galaxies below the detection threshold. In the second case, this would correspond for this cluster to an additional flux of $\sim 10 \mu\text{Jy}$, or about $\sim 60 M_\odot \text{ yr}^{-1}$ for main sequence (MS) galaxies at the cluster redshift (Magdis et al. 2012). This would represent $\sim 8\%$ of the SFR within the region covered by the SZ signal (C18), considering cluster members and interlopers. For comparison, this corresponds to three $\sim 10^{10} M_\odot$ MS galaxies at the redshift of the cluster or 30–40 $10^9 M_\odot$ galaxies (Schreiber et al. 2015). The mass completeness limit of our deepest near-infrared imaging being $\sim 10^{10} M_\odot$ (Strazzullo et al. 2013), it is not impossible that a few galaxies might have been missed even in the priors catalogue. Diffuse emission could also provide another source of positive signal at slightly larger scales. In addition to its hot ICM and giant Ly α nebula, C11449 also hosts intracluster light (ICL), on a similar scale to the Ly α emission and possibly of stellar origin (Dimauro et al., in prep.). Thermal emission from intracluster dust might have been detected at lower redshift (however, the low resolution of the data makes it unclear; Planck Intermediate Results XLIII), although constraints on the gas-to-dust ratio of the ICM place it at a much lower level than in star forming galaxies (Kitayama et al. 2009; Gutiérrez & López-Corredoira 2017). However, since C11449 is in a much younger dynamical state, as also evidenced by its relatively bright ICL, its FIR emission could be comparatively higher.

On the other hand, if the lack of negative power at $uv > 30 \text{ m}$ is an intrinsic property of the SZ signal, it suggests lower central electron density and/or temperature with respect to lower-redshift clusters. This could either simply reflect a secular evolution in clusters' ICM pressure distribution or be the result of feedback effects from galaxies. In the latter case, AGN-generated cavities in the ICM, for example, typically have lower electron density and pressure than the thermal ICM, leading to a decreased signal with respect to the thermal case (e.g., Pfrommer et al. 2005; Ehlert et al. 2019; Abdulla et al. 2019). It would not be entirely surprising for one to be present in C11449, as the cluster hosts at least two X-ray detected AGNs, whose putative outflows are likely associated with the powering and/or maintenance of the Ly α emission nebula in its core (Valentino et al. 2016). Furthermore, while the extent of the “flat” pressure region necessary to reproduce the observed profile is large, of the order of $\sim 100 \text{ kpc}$, it is not unheard of in clusters (e.g., Abdulla et al. 2019). One might therefore find it puzzling that the McD14 and A10 models, which assume no baryonic physics, match the observed profile and X-ray mass constraint better than the AGN 8.0 and AGN 8.5 models, which include them. Additionally, these models were calibrated on $z \sim 0$ data and assume self-similar evolution with redshift, as do the scaling relations (Leauthaud et al. 2010) used in the *Chandra* analysis. Contrarily, more recent work suggest that the assumption of self-similarity does not quite hold when AGN feedback is considered (Le Brun et al. 2017).

Finally, we note that a deviation from axisymmetry in the SZ signal, such as non-zero ellipticity, imply that either of the effects discussed above (or combination thereof) would be stronger, as it would transfer power to smaller scales, i.e., flatten

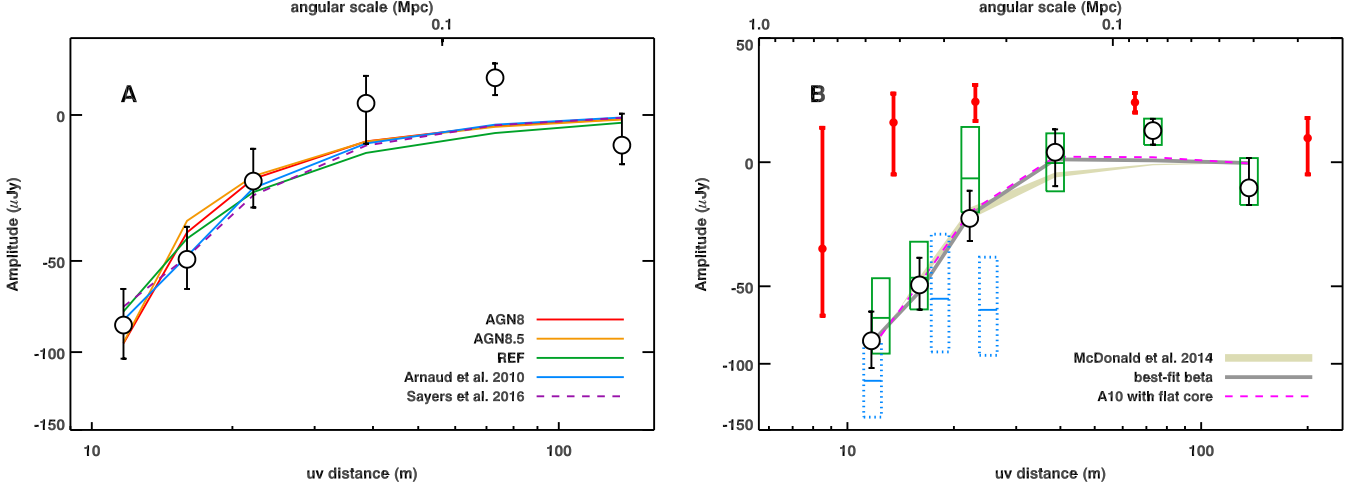

Fig. 3. A: Amplitude of the SZ decrement as a function of baseline length and physical scale for the combined ALMA+ACA dataset (empty white circles with error bars), after subtraction of positive sources (active galaxies). For comparison, coloured lines show rescaled theoretical models with different feedback schemes from LB15 as well as a rescaled empirical pressure profile of local clusters from A10, including the modified outer slope from S16. B: same data, with best-fit β -model. The solid green and dotted blue rectangles show the individual ALMA and ACA uv -amplitude profile and noise, respectively, while the red points with error bars show the combined amplitudes *before* subtraction of positive point sources. The tan curve shows the range covered by the McD14 best-fit models, while the magenta dashed one shows a composite model using the A10 profile at $> 7''$ and a flat signal in the inner $7''$.

Fig. 4. Total mass constraints obtained from fitting the observed uv -amplitude profile with theoretical/empirical models (Fig. 3, A), as a function of the confidence of the fit derived from the χ^2 . The grey horizontal stripe shows the 1σ Chandra mass constraint, for comparison.

the uv -amplitude profile. The excellent agreement between the observed profile and models shown in Fig. 3 (B) suggests however that the SZ decrement of the cluster has a fairly circular geometry. On the other hand, no elliptical or multi-component fit was attempted given the S/N of the data. Even with ALMA, we are, in the $z \sim 2$ regime, probing the limits of the recoverable information. The r.m.s. noise of the ALMA data and the lack of detectable structure in its residuals after subtracting both the point sources and the SZ signal (as shown in Fig. 6) allows us to put a 3σ upper-limit on individual inhomogeneities in the SZ signal of $\sim 6\%$ of the total decrement. However, lower-amplitude pressure discontinuities might still be present. The current data nevertheless provide an interesting baseline for comparison with future observations of similar or higher-redshift galaxy clusters,

such as Cl J1001+0220 at $z = 2.5$ (Wang et al. 2016), in which feedback from highly-active galaxies is expected to be strong. Conversely, averaging the SZ signal over a population of high-redshift galaxy clusters, by increasing the S/N and minimising cosmic variance, would allow us to set true constraints on ICM pressure models at early stages of cluster formation.

Fig. 5. Best-fit β model (black curve) and 1σ confidence envelope (grey). For comparison, the A10 and average McD14 models are shown in blue and magenta, respectively, and the spatial range probed by ALMA and ACA by light and dark tan regions.

5. Conclusions

Combined ALMA and ACA observations of Cl1449 at 92 GHz have yielded a secure $\sim 5\sigma$ detection of the SZ decrement associated with its ICM. Comparing the uv -amplitude profile of the SZ signal to a variety of pressure models, we confirm the total mass

Fig. 6. ALMA 92 GHz residual image, after subtracting both the point sources and the SZ signal, with the same field of view as panels A, B, and D of Fig. 2. For comparison, the white dashed contours mark the position of the SZ signal as shown in panels C and D of Fig. 2. The white-filled magenta ellipse shows the size of the synthesised ALMA beam.

estimates obtained from *Chandra* X-ray observations of the cluster. While the SZ signal provides independent constraints, these still depend on the adopted model and its calibration. We find a factor ~ 2 spread in mass estimates among models at similar significance levels, with the SZ constraints nevertheless clustering around the mass inferred from *Chandra* X-ray data.

In this work we measure the 92 GHz flux of galaxies in the cluster’s field and subtract it from the complex visibilities, i.e., in the Fourier space of the data. We perform the rest of the analysis entirely on the visibilities, rebinning them into a uv -amplitude profile. The final S/N of the data, conservatively estimated, is not quite high enough to strongly constrain ICM pressure models. We see no sign of a cool core and, while the empirical $z < 0.2$ Arnaud et al. (2010) profile appears to hold on here as well, we notice a small tension between the data and locally-calibrated models. This could either be produced by residuals from the subtraction of positive sources or might reflect a pressure deficit in parts of the cluster’s ICM compared to expectations, as suggested by the redshift trend seen in less distant and more massive clusters. Distinguishing between these two scenarios is not possible with the current data.

The density of star formation present within C11449 is sufficient to almost entirely fill the SZ decrement unless corrected for. This issue is likely to affect all $z \gtrsim 2$ clusters and to grow in severity with redshift due to both the increased activity of galaxies within cluster cores (e.g., Wang et al. 2016, 2018) and the negative K -correction of their FIR dust emission at the frequencies of the SZ effect. It can nevertheless be slightly minimised by observing at lower frequencies, since at $z > 2$ the tail of dust emission in galaxies falls somewhat steeper than the SZ decrement. For example, we would expect in the case of

C11449 a $\sim 30\%$ improvement in contrast when observing with ALMA/ACA in Band 1 (~ 40 GHz; not yet commissioned at the time of writing) instead of Band 3. At $z \sim 2.5$, on the other hand, the gain would be closer to $\sim 80\%$. Although the SZ signal in Band 1 is also expected to be lower by a third compared to that in Band 3, it will be sampled by a beam a factor ~ 3 larger. A simple calculation using our best fitting profile and the noise predictions from the current exposure time calculator then suggests that we can reach a comparable S/N at 40 GHz with the same integration time as for 92 GHz, but with considerably less uncertainty on the contamination from positive emitters.

Our observation of the lowest mass single SZ detection so far demonstrates the power of ALMA for the study of the ICM of emerging galaxy clusters. It also illustrates the usefulness of combining short- and long-baseline interferometric observations in the context of SZ surveys. Indeed, the necessity for point-source subtraction, which requires a good prior knowledge of FIR emitters in the target field, as well as the increasing activity of cluster galaxies as we peer further back in time, casts doubts on the viability of single-dish telescopes for high-redshift SZ surveys. In this case multi-band observations would be absolutely necessary, as well as a high S/N to compensate for the steeply rising FIR SED of star forming galaxies, in both frequency and redshift, with respect to the SZ signal. However, this might still not be sufficient without accurate redshift information, as such observations could be susceptible to degeneracies between the spectral shape of the SZ signal and the line-of-sight distribution of FIR emitters. We can thus expect a significant and increasing number of structures to be misidentified or missed entirely due to star formation filling their decrement, suggesting that any SZ census of $z \sim 2$ clusters is at risk of being biased towards older galaxy populations rather than simply higher relative total masses.

Acknowledgements. We thank the anonymous referee for their constructive report, which helped improve the presentation of this work. This work is based on data from ALMA program 2016.1.01107, as well as programs 2012.1.00885.S and 2015.1.01355.S. ALMA is a partnership of ESO (representing its member states), NSF (USA) and NINS (Japan), together with NRC (Canada), MOST and ASIAA (Taiwan), and KASI (Republic of Korea), in co-operation with the Republic of Chile. Appendix A: 92 GHz continuum sources

Table A.1 shows the 92 GHz fluxes of known FIR sources in the field of C11449, measured on our ALMA data. We compare these to the predictions of Magdis et al. (2012) templates (Fig. A.1), assuming MS SEDs based on the overall consistency between the MS at $z \sim 2$ and the SFRs derived by C18.

Table A.1. Known 92 GHz emitters in the field of C11449, after correcting for the primary beam

ID*	R.A. deg	Dec deg	Flux μ Jy	Flux error μ Jy
A1+B1**	222.30882	8.94054	26.5	3.6
A5	222.30963	8.93690	56.1	4.0
6**	222.30991	8.93779	11.6	3.8
BRG	222.31526	8.94785	255.2	8.5
A2**	222.30710	8.93951	10.3	3.6
A3	222.30488	8.93820	14.6	4.0
A4	222.30648	8.93778	19.0	3.9
13**	222.30856	8.94199	5.7	3.6
N7+S7**	222.31025	8.93985	4.1	3.6

* identifiers in C18, except for BRG which denotes a bright, low-redshift radio galaxy outside the field of the data discussed in that paper. Given the lower resolution of our ALMA data, some close sources in C18 were merged for the purpose of 92 GHz subtraction. ** confirmed cluster members.

Fig. A.1. Comparison between the subtracted 92 GHz fluxes of sources, i.e., measured from the ALMA data, and the fluxes predicted by Magdis et al. (2012) MS SED templates, based on the SFR of the sources derived in C18 from CO fluxes. Only sources for which a redshift estimate (photometric or spectroscopic) is available are shown.

Appendix B: Peak offset significance

To investigate the significance of the observed offset between the positions of the peaks of the SZ and X-ray signals, we carry out a simple Monte Carlo simulation using a simulated SZ decrement based on the A10 pressure model and best-fit total mass value for C11449 (see Section 3.1). We take the Fourier transform of this model, according to Eq. E.1 and add noise to the model complex visibilities based on the weights of the observed ones, assuming natural weighting, and merge the ACA and ALMA simulated observations. We then perform a point-source extraction with

free position, as described in Section 3, which we compare to the observed offsets. In the case of the X-ray centroid, we consider both the combined astrometric uncertainty of ALMA/ACA and *Chandra* ($\sim 1''$) and a more realistic $5''$ precision appropriate for the extended emission (Valentino et al. 2016). As shown in Fig. B.1, we find different probabilities for the SZ-BCG and SZ-X-ray offsets, with the latter falling within the top 1.5-5% of realisations.

Fig. B.1. Cumulative distributions of the positional offset between the true and recovered peak of the SZ signal. These are based on Monte Carlo simulations using the (u, v) sampling of the data visibilities, assuming a noise consistent with the observed one and using a Arnaud et al. (2010) pressure model with a total mass of $6 \times 10^{13} M_{\odot}$. The grey band (dashed vertical line) shows the offset between the positions of the SZ and X-ray peaks (respectively, BCG).

Appendix C: 31 GHz observations

C11449 was observed at 31 GHz with CARMA between March and April 2012, using the 3.5 m sub-array in the SL configuration (project c0865; PI Riechers). This consisted of 6 antennas in a <20 m close-packed configuration probing $\sim 2'$ scales, and 2 outrigger antennas to add baselines of >50 m and provide $\sim 0.3'$ resolution for point-source subtraction, for a total baseline range of ~ 4 –83 m. The observation covered 11 tracks, resulting in a combined on-source observing time of 31.4 h. Bandpass calibration was performed during each track using the quasars J1512–090 and 3C 279, and complex gain calibration using the radio quasar J1504+104. The planet Mars was used as the primary flux calibrator. The data were then reduced using the Miriad (Sault et al. 1995) software package. Imaging with natural baseline weighting results in a synthesised beam size of $135'' \times 123''$, while uniform baseline weighting provides a $22'' \times 16''$ beam (for comparison, the primary beam FWHM of the 3.5 m antennas is $\sim 11'$ at 31 GHz). We find a continuum r.m.s. noise limit of 90μ Jy/beam across the full 8 GHz bandwidth.

Here we fit point sources using the long-baseline data ($uv > 50$ m) from the outrigger antennas and subtract them from all visibilities. When extrapolating the 92 GHz $\sim 190 \mu$ Jy signal assuming a standard spectral shape for the thermal SZ effect, the decrement at 31 GHz should be $\sim 32 \mu$ Jy. Consequently we see no detectable signal, as expected given the noise of the data. We nevertheless fit the visibilities with the best-fit model to the

92 GHz data (see Section 4) at fixed positions corresponding to either the cluster’s centre of mass or the peak of the 92 GHz decrement. We find $0 \pm 120 \mu\text{Jy}$, which implies a 3σ “upper” limit to the 31 GHz signal of $\sim 360 \mu\text{Jy}$ (i.e., about ten times the expectation value).

Appendix D: Lensed background

Gravitational lensing of background sources by the halo of a galaxy cluster can affect its observed SZ decrement in at least two ways: boosting of their flux, which contributes to the filling of the decrement, and number count depletion by reducing their surface density, which can add signal to the decrement. Here we assume that background sources boosted above the detection limit will be identified and subtracted, and therefore concentrate on the second effect. In this case, the surface brightness of undetected sources (i.e., the background) Σ_{IB} can be written as a function of the observed-luminosity function $N(S, z)$ and detection threshold S_{det} :

$$\Sigma_{\text{IB}}(\theta)dz = \mu(\theta)^{-1}dz \int^{S_{\text{det}}/\mu(\theta)} N(S, z > z_{\text{cluster}}) S dS, \quad (\text{D.1})$$

where $\mu(\theta)$ is the magnification at angular distance θ from the halo’s centre (see, e.g., Broadhurst et al. 1995; Wright & Brainerd 2000; Umetsu et al. 2014), assuming spherical symmetry. As $\mu(\theta)$ increases with decreasing θ , the infrared background also decreases towards the cluster’s centre with respect to the unlensed ($\mu = 1$) case at large radii (e.g., Zemcov et al. 2013; Sayers et al. 2018). Here we use the 3 mm number counts distribution of Zavala et al. (2018), extrapolating it to arbitrarily low fluxes, the redshift distribution of sub-millimetre galaxies of Weiß et al. (2013, we assume that the number counts distribution is independent of redshift), and a detection limit of five times our ACA r.m.s. Even under this latter conservative assumption (the detection limits of both C18 and our ALMA data being lower) we find that the contribution of the integrated lensed 3 mm background to the total decrement is negligible compared to the SZ one, as shown in Fig. D.1.

Fig. D.1. Relative amplitude difference, as a function of uv -distance, between simulated observations of models with (“ A_{IB} ”) and without (“ A ”) the additional decrement due to lensing-induced number count depletion of undetected 3 mm emitters. As in Fig. E.1, the error bars show the r.m.s. deviations between model visibilities.

Appendix E: uv plane modelling

For single-pointing observations, the complex visibilities can be approximated as

$$V(u, v) = \iint B(x, y) M(x, y) e^{2\pi i(ux+vy)} dx dy, \quad (\text{E.1})$$

where M is the on-sky intensity distribution of the model and B the primary beam response of the antennae. We compare this to the output of noise-free (pwv=0 option in `simalma`) simulated `simalma` observations, using the GNFW models described in Section 3.1. We find a relative difference between both of at most $\sim 4\%$ (Fig. E.1), which is well below the noise level of our data. The approximation given in Equation E.1 therefore allows us to quickly explore the parameter space of models at little to no cost of precision, given our S/N (see Fig. 3). On the other hand, while the full observation model used by `simalma` is certainly more accurate, a single iteration requires significantly more time and thus makes automation less feasible.

Fig. E.1. Relative amplitude difference, as a function of uv -distance, between the output of noise-free simulated observations of parametric models (see main text) done with the `simalma` task of the CASA software and simpler Fourier transforms of the same models (with primary beam attenuation) interpolated at the same (u, v) coordinates. The error bars show the r.m.s. deviations between model visibilities computed with both methods.

Appendix F: β -model fit

To explore a larger range of pressure profiles we substitute, in the method described in Section 3.1, the GNFW profiles with a deprojected β -model for the gas density:

$$P(r) = P_0 \left[1 + \left(\frac{r}{r_c} \right)^2 \right]^{-3\beta/2}, \quad (\text{F.1})$$

where r_c is the core radius and β the outer slope of the model. We then assume primordial abundances and assume the gas fraction and temperature model A from Dvorkin & Rephaeli (2015). We use an expanding parameter grid with $(r_c > 0.1, \beta > 0.1)$ and steps of $(\Delta r_c, \Delta \beta) = (0.01, 0.01)$. The result of the fit is shown in Fig. F.1.

Fig. F.1. χ^2 confidence intervals for the parameters (core radius r_c and index β) of the β -model fit to the uv -amplitude profile. The dark to light shaded regions show, respectively, the 1σ -, 2σ -, and 3σ confidence intervals.
